

A MICROCOMPUTER BASED FINANCIAL RECORD MANAGEMENT  
SYSTEM FOR PRODUCTION AGRICULTURE

by

William Scott Watson

An Abstract

Of a thesis submitted in partial fulfillment of the  
requirements for the degree of Master of Science  
in the School of Applied Sciences and Technology  
Central Missouri State University

November 1982

Thesis supervisor: Associate Professor Richard Tabor

As profit margins for agricultural products become narrower, the successful farm operator must maximize the efficiency of their management techniques. While carefully maintained manual bookkeeping systems can help identify weaknesses in the farming enterprise, the labor intensive nature of these systems rarely insures the timeliness of the information they produce. The scope of this thesis is to interface existing farm management financial record bookkeeping systems with the ease of use, dependability, and fast processing speed of a microcomputer.

While no original bookkeeping principles were utilized in this software package, certain abilities were incorporated that are generally considered too time consuming to be practical with manual bookkeeping systems. These abilities include:

1. The ability to manage and report information for more than one agricultural enterprise.
2. The ability to manage and report information for more than one bank account.
3. The ability to manage and report information for more than one farm operator.
4. The ability to collate various bookkeeping information to produce financial end-of-year analysis.
5. A degree of user friendliness that allows untrained users to operate the system with confidence.
6. Only information important to the user is displayed on the video screen or lineprinter.

Complex data and program manipulations are not apparent to the user in order to avoid confusion.

The package was written using Disk BASIC computer language on a 48K Model I TRS-80 microcomputer with two five and one quarter inch mini-floppy diskette drives and one parallel interface eighty column lineprinter.

### Microprocessor And Peripheral Operation

The software presented in this thesis is designed to execute in a specific hardware environment. While translation of the software and substitution of the hardware is certainly possible, the following is a list of the necessary hardware to insure proper operation of the software as presented:

1. Radio Shack TRS-80 Model I or Model III microcomputer.
2. Parallel interfaced eighty column lineprinter.
3. Two double density, single sided, five and one quarter inch mini-floppy diskette drives.

The TRS-80 microcomputer utilizes a Zilog model Z-80 microprocessor as its central processing unit. The Z-80 has an eight bit data bus and a sixteen bit address bus, giving it the capacity to address a total of 65,536 eight-bit bytes. The native logic of all components of the TRS-80 is binary (or base two). All programs executed by the Z-80 must be encoded in memory as binary information.

Binary information, while inconvenient to humans as a number system, is essential to all microprocessor applications. In electronic format, the numbers one and zero are represented by the presence or non-presence of electricity at a given instant at a specific location. For purposes of nomenclature, a location which may contain a one or a zero electronically is termed a bit. By placing bits side-by-side, a larger number can be represented. In order to convert binary numbers to their decimal equivalents

it is necessary to understand how the binary number system operates.

As an example, suppose a four-bit binary number exists in an electronic circuit with a value of  $1101_2$  (the subscripted number implies the number base of the numerals; in this case, the subscripted '2' shows that 1101 is a binary number). In order to convert this value to decimal (base 10) equivalent, each bit must be converted to decimal individually. First, consider the decimal number 2,547. If this number is dissected one digit at a time from right to left we find:

$$7 \times 10^0 = 7$$

$$4 \times 10^1 = 40$$

$$5 \times 10^2 = 500$$

$$2 \times 10^3 = 2,000$$

$$\text{Therefore: } 2,000 + 500 + 40 + 7 = 2,547$$

If this same process is executed on the binary number above:

$$1 \times 2^0 = 1_{10}$$

$$0 \times 2^1 = 0_{10}$$

$$1 \times 2^2 = 4_{10}$$

$$1 \times 2^3 = 8_{10}$$

$$\text{Therefore: } 8 + 4 + 0 + 1 = 13_{10}$$

By observation, the largest number that four binary bits can represent is  $1111_2$  which would equal  $15_{10}$ . As mentioned earlier, the Z-80 has a data bus of eight bits. The data bus width limits the largest number that can be passed to or from the central processing unit (or CPU) at one time. This places the numerical

range of the Z-80 at  $0_{10}$  to  $255_{10}$  (since  $11111111_2$  equals  $255_{10}$ ). The address bus determines how many memory locations can be accessed by the CPU for passing data. The sixteen bit wide address bus of the Z-80 allows up to 65,536 locations of memory to be accessible by the CPU. Again, as a matter of nomenclature, the number of bits assigned to a memory location is termed a byte. Since the data bus of the Z-80 is eight bits wide, it would be inefficient to use more or less than eight bits per byte. Thus, the TRS-80 uses eight-bit bytes as do nearly all other microcomputers. Progressive technology in the microprocessor field has produced a new generation of microprocessors which have a sixteen bit data bus and a thirty two bit address bus.

Memory can be defined as simply as a large collection of bits. It is up to the microprocessor to use the bits intelligently for storing data. In the TRS-80, memory is arranged in groups of eight bits, each group given an identifying number, called the address. Addresses are assigned in a sequential manner, beginning with memory location zero and ending with memory location 65,535. It is important to note here that memory is generally referred to in quantities of 'K'. While 'K' is the metric system abbreviation for one thousand, in computers 'K' is given the closest binary equivalent, 1024 (which is two to the tenth power). Therefore, we would refer to a computer having 65,536 bytes of memory (64 X 1024 bytes) as a '64K' computer.

Even though memory is given sequential addresses, the CPU does not have to search through the first 42,000 bytes to find the value of address 42,001. By simply placing the binary

equivalent on the address bus ( $42,000_{10} = 1011011000010001_2$ ), the CPU can access the contents of that address directly. Because of this characteristic, this sort of memory is termed Direct Access Memory, or more commonly, Random Access Memory (RAM).

When power is first applied to the microprocessor, execution of an assumed program immediately begins at address zero. If no deliberate program instruction has been placed in this memory location the microprocessor will execute whatever random instruction does exist, and will continue to do so sequentially through memory indefinitely.

The Z-80 microprocessor has an instruction set of over 500 commands. While this may seem a large number, each command performs a somewhat primitive action, such as a branch in execution address, a simple addition, or a test of a single bit. Instructions exist as a series of one, two, three, or four bytes, depending on their relative complexity. For example, a single byte instruction is  $00000000_2$ . This number refers to a specific instruction called No Operation. By the value of the first byte, the microprocessor knows if the instruction is a single byte instruction, or if further bytes need to be loaded to complete the instruction. Data is placed in memory the same way. Since the microprocessor cannot differentiate between program instruction bytes and data bytes, and error in program logic can cause disastrous results- causing the CPU to execute data values as if they were program instructions. Program instructions that can be processed directly by the microprocessor comprise an instruction set referred to as machine language.

Obviously, coding a machine language program by hand is a tedious and error-prone chore. The first high level language was written in order to solve this problem. In this language the individual instructions were given abbreviated labels. In the case of the No Operation instruction ( $00000000_2$ ), the symbol NOP was assigned. Since these labels are easier to memorize and use than groups of binary digits, programming time was more efficiently used. Since the letters NOP are meaningless to a microprocessor, it was the duty of this language to translate these instruction symbols into their meaningful binary equivalents. This language was termed assembly language, and the actual program that did the translation was called the assembler.

Even though machine language instructions execute at incredible speeds (on the order of nanoseconds in the TRS-80), it is very difficult to write machine language programs because of the primitive nature of the instruction set and the inconvenient manner of numeric manipulation. The simple concept of floating point decimal numbers can take thousands of machine language instructions to emulate. Therefore, it became necessary to construct even higher level languages. Examples of these languages include FORTRAN, COBOL, and most recently, BASIC.

These languages became popular for several reasons. They were more English-like in their instruction sets, they performed difficult tasks with few commands, and they reduced the time necessary to train programmers. Even though these languages execute slower than pure machine language programs, it takes much less time to write the program and insure that it is operating correctly. Each of these languages is nothing more

than a computer program, designed to translate groups of symbols into machine language instructions.

Whenever electric power is applied to the TRS-80, a program called BASIC is immediately executed. This program is stored in a special non-volatile type of memory which has been addressed to the lowest 16K of memory. While random access memory loses its contents when power is turned off, BASIC is permanently burned into a type of memory called Read Only Memory (ROM). ROM does not lose its contents when power is turned off, and the contents of ROM cannot be changed once a program has been electrically burned into it. Thus, the TRS-80 operator does not have to learn complicated power-up procedures or key in BASIC by hand each time the computer is used. While it does limit the amount of memory that can be used for programs, it is a small trade for the convenience and power of a high level language such as BASIC.

It is for this reason that confusion exists about how much memory a fully expanded TRS-80 contains. A fully expanded TRS-80 is usually sold by the label '48K'. This refers only to the 48K bytes of memory available for user programs. Including the dedicated lower 16K of ROM, the computer actually contains a total of 64K bytes of memory.

RAM and ROM are not the only types of mass storage available to the microcomputer. Indeed, it would be unfortunate if a program would have to be retyped into the computer each time the power was disconnected. The most popular forms of mass storage for the TRS-80 are cassette tape and mini-floppy diskettes. An additional mass storage device would be a lineprinter. Even

though information cannot be reentered to the computer from a printout, it is a valid form of information storage.

The electronically simple processes of operating a cassette recorder and lineprinter are actually short enough to be included within the BASIC language. The more elaborate mini-floppy diskette drives require so many instructions to operate that a language separate from BASIC had to be written just for the use of the disk drives. When BASIC first begins to execute upon power-up, it electronically checks to see if a mini-floppy disk drive is connected to the computer. If it finds at least one disk drive connected it begins a special program sequence. If it does not find a disk drive connected, BASIC continues its power-up sequence as normal.

The special program sequence executed when a disk drive is detected is known as a boot sequence; a term derived from the phrase "picking oneself up by the bootstraps". During the boot sequence, execution of BASIC is aborted, the disk drive is turned on, and a special program called the Disk Operating System or DOS is loaded into the computer and executed. DOS (pronounced to rhyme with boss) contains several programs designed to fully utilize the capabilities of the mini-floppy disk drive.

In addition DOS contains a small program called Disk BASIC. Disk BASIC interfaces with the resident ROM BASIC adding several commands to use the mini-floppy disk drive to save and load programs as well as to facilitate storage and retrieval of data files. However, since at least part of DOS, and probably Disk BASIC will be in memory, the amount of user available memory is lowered to around 32K in a fully expanded system.

The method by which data is encoded on a mini-floppy diskette is of prime concern to the programmer. A mini-floppy diskette is divided into forty concentric circles, called tracks. Each track is divided into a variable number of pie-shaped wedges which are called sectors. For the TRS-80 mini-floppy diskette operating at double density, each track is divided into sixteen sectors of 256 bytes each. Therefore, a mini-floppy diskette would have the capacity of 163,840 bytes of storage. For a computer having only one disk drive part of that storage space will be dedicated to DOS. However, each additional disk drive would have the full 163,840 bytes available to the user as storage space.

One track of each diskette is reserved for the diskette's directory. The directory instructs DOS where on the disk certain programs or files are located. In addition, the directory maintains a table of free space available, and where it is located on the diskette. For this table, each track is split in half and that group of eight sectors is called a granule. The free space map keeps track of each granule's status- whether it is being used or not. If a data file containing only seven bytes of data were to be stored on the diskette, an entire granule of 2,048 bytes would still be allocated to the file.

In order to operate properly, the software presented in this thesis relies upon the above hardware environment. Since all programs are written using Disk BASIC, it is not recommended that any of the above hardware specifications be changed without full understanding of the software.

## DOS Operation

From a hardware view, microcomputers may seem an intricate world of binary and acronyms. However, the ultimate goal of a sound computer program is to be easily understood and used by persons untrained in microprocessor and peripheral operation. Again, it is the duty of the programmer to utilize the computer's power to simplify the task of the end user. Since the software presented in this thesis heavily depends on fast, error free disk operation, a short discussion of disk software operation is presented here.

As mentioned earlier, a mini-floppy diskette may contain both program or data files. The type of file on the diskette is identified by information in the diskette's directory. Each file, whether it is a program or data file, is given a descriptive name. This name may be up to eight characters in length, and may contain both letters and numbers as long as the first character is a letter. In addition, the program name is given an extension which may be up to three characters in length. An extension tells the disk user what type of file it is (program or data).

In the disk directory, the program name and extension are separated by a backslash ('\') character. It is left to the programmer to be consistent in extension names to avoid confusion at a later date. There are three uniform extensions used by the software in this thesis:

1. BAS - identifies file as a BASIC program.
2. CMD - identifies file as a machine language program.
3. DAT - identifies file as a data file.

Therefore, a directory entry called EDITOR/BAS would show there is a file on this diskette called EDITOR and it is a BASIC program. Likewise, an entry called NAMES/DAT would show there is a file called NAMES and it is a sequential data file. Although several other conventional extension names exist, these are the only ones used by the programs in this thesis.

There are only three Disk BASIC commands which govern the use of BASIC programs: LOAD, RUN, and SAVE. Each of these commands require a target file specification placed in quotes, such as the command LOAD "EDITOR/BAS". In addition, a disk drive number can be specified at the end of the file specification to speed up searching for the file. An example of this is: LOAD "EDITOR/BAS:0".

The SAVE "FILESPEC" command would magnetically write on the diskette contained in the specified drive (or the first drive found to have free space if no drive number is specified) whatever BASIC program is in memory at that time. The LOAD "FILESPEC" command would retrieve a previously stored program and place it into memory, ready to execute. The RUN "FILESPEC" command functions exactly as the LOAD "FILESPEC" command, but execution of the program begins automatically after it has been loaded into memory. Using just these three commands, all BASIC program manipulation is accomplished.

Data file manipulation is not quite as straightforward as BASIC program manipulation. The sequential data file has a first-in-first-out (FIFO) access arrangement. That is, to read the fifty first data record in a sequential data file, the first

fifty records would have to be read in and discarded. The file is made accessible to the BASIC program by a command called OPEN. The OPEN command must specify whether the data file is to be input from or output to because DOS will not allow data to be moving in opposite directions simultaneously. In order to change a file access from input to output, or vice versa, the file must be closed using the command CLOSE and then reopened with the desired specification of data movement direction.

The largest limitation of the sequential data file is the inability to easily edit mistakes from the file. Since information cannot be inserted or deleted from the middle of a data file, a copy of the file must be made with the corrections placed in the copy. Then the old file is destroyed and the new file is renamed the old file's directory name. Fortunately, DOS does allow new data to be added to the end of a sequential data file.

The nature of sequential data files defines its use for data that once entered does not change. A permanent file of receipts or check stubs, as used by the programs in this thesis, would meet this criterion.

### Program Overview

The programs presented in this thesis require a diskette storage space of approximately 125,000 bytes, and an execution memory (RAM) of nearly 250,000 bytes. Since this is more memory than is available on a fully expanded (48K RAM) TRS-80, a chained module method of execution was incorporated.

The chained module method splits the overall function of the package into its integral parts. A separate program is used to maintain each of these parts, and a menu driven selection scheme allows the user to select the appropriate program for the desired task. When a particular task is completed, the menu program is executed, and the user can select the next desired task. An important consideration for the use of chained program modules is not to allow any single program to occupy more memory than is available.

Two disk drives are used in the execution of this package. One drive is used to hold the program diskette, while the other is used for storage and manipulation of data files. Two small data files are kept on the program diskette, however, to identify the diskette and the current configuration of the package. This was necessary since the programs needed more storage space than is available on a single diskette, and were divided into two program diskettes. The identification file thus instructs the menu program which of the program diskettes is currently in the disk drive so that a diskette switch could be made if necessary.

The configuration file is a vital part of the package, its function being to customize the package to the individual requirements of the user. This file is accessed by nearly all of the programs in the package constantly, so the placement of the configuration file on the program disk was done to increase efficiency. The configuration file contains the codes and descriptions of all expense and receipt account categories, codes and descriptions of all enterprises, codes and descriptions of all bank accounts, and codes and descriptions of all farm operators.

Three types of data files are used by this system: receipts, expenses, and special. A different diskette is used for each type of file. Each of these diskettes has an identification file to instruct programs whether the correct data diskette is in the disk drive for the particular job being executed. This method is used to keep the various data separated and eliminate the possibility of incorrect data being stored on a data diskette. The special data diskette is used for all data not associated with receipts and expenses. Examples of this data would be inventories, capital gains records, and depreciation schedules.

For security, the identification files on both data and program diskettes are similar in structure. This eliminates the possibility of accidental placement of a program disk in the data drive, and having data written over important programs. Before any data is written to a diskette, its identification file is interrogated. If the wrong diskette is inserted, the user is alerted and given the opportunity to correct the mistake.

At any time, the user may abort a specific job and return to the menu. In addition, the identification file allows the data file to actually span more than one physical diskette, that is, a receipts file can be as long as the user needs. No limits are placed on the number of entries that can be made to a data file. When a certain number of entries have been stored in a data file, the user is instructed to initialize a new data diskette.

### Program Operation

The scope of this thesis is the construction of a financial record management system for production agriculture implemented on a microcomputer. Actual information manipulation is no different in this system than in conventional manual bookkeeping systems. The particular bookkeeping system emulated in this system is the Ohio State University Commercial Farm Account Record Book. Because of the flexibility of the configuration file used by the computerized bookkeeping system, it is compatible with any manual bookkeeping system for agricultural use.

In addition to providing timely information by virtue of the computer's extremely fast processing abilities, the package was designed to include the following abilities:

1. Ability to manage and report information for more than one agricultural enterprise.
2. Ability to manage and report information for more than one bank account.
3. Ability to manage and report information for more than one farm operator.
4. Ability to collate various information to provide end-of-year financial evaluation of any of the above criteria or the operation as a whole. This information includes debit and credit summary for each receipt and expense account category, depreciation schedules, and net worth statement.

5. A degree of user friendliness that allows untrained users to operate the system with confidence.
6. Complex data and program manipulations must not be apparent to the user to avoid confusion. Only information important to the user is displayed on the video screen or lineprinter.

The configuration file used by the system is defined by the user, as well as fiscal year information. This allows a user to adapt the system to the manual system that is most familiar to them. In addition, the user may expand the configuration to include features that manual systems do not employ, such as enterprise and bank account cross referencing reports. The ultimate goal of this project was to provide a record management system so flexible that a user could easily generate any cross reference of the data entered into the system. For instance, a valid report might be the amount of veterinary bills used for a swine operation which were paid by cash between the dates of February 23 and June 15.

Each of the program modules in the package perform a specific function. The following is a description of each of the programs included in the package.

ANALYSIS/BAS - This program surveys and collates all credit and debit information to produce a profit or loss statement.

BACK/BAS - This program provides a means to make backup copies of data diskettes- a necessary function of good data processing operation.

CGMEBF/BAS - This program stores and prints out a record of Capital Gains For Machinery, Equipment, Buildings, and Farm Land.

CGPBLSD/BAS - This program stores and prints out a record of Capital Gains For Purchased Breeding Livestock Sold Or Died.

CGRBL/BAS - This program stores and prints out a record of Capital Gains For Raised Breeding Livestock.

CONFIG/BAS - This is the largest program in the package due to its enormous flexibility. The function of this program is to configure the bookkeeping parameters based upon the preference of the user. From this information a file entitled CONFIG/DAT is placed on both program diskettes and is accessed by any program that performs a bookkeeping function. This program can be used to create CONFIG/DAT, add or delete items from CONFIG/DAT, print out a hardcopy record of CONFIG/DAT, sort CONFIG/DAT by code number, or sort CONFIG/DAT alphabetically

DEPREC/BAS - This program stores a permanent depreciation schedule for depreciable items on the farm. Although the program does not calculate actual depreciation schedules, the information is necessary to perform end-of-year analysis.

EDITOR/BAS - This progra allows the user to correct mistakes in a receipts or expenses data file. The program can display entries, delete entries, restore deleted entries, or purge a data diskette of deleted entries to make room for additional entries on that diskette.

EXPENSES/BAS - This program is used to enter and store expenses incurred. All expense entries are made to the EXPENSES data disk and the information file is updated to show the current number of expense entries in the file.

FINVEN/BAS - This program stores or prints out a record of Inventory of Feed, Crops, and Supplies. Like other inventories and capital gains records, this data is placed on the SPECIAL data diskette.

FISCAL/BAS - This program allows the user to customize the package to perform end-of-year analysis based on the fiscal year dates used by that farm operation. This data is placed in a file called FISCAL/DAT and stored on the SPECIAL data diskette.

INIT/BAS - This program allows the user to create a new RECEIPTS, EXPENSES, or SPECIAL data diskette. An identification file entitled HEADER/DAT contains either the word RECEIPTS, EXPENSES, or SPECIAL in order to alert bookkeeping programs which type of data diskette has been placed in a disk drive.

MASTER/BAS - This is the program which acts as a menu to select other programs in the package. Upon power-up, this program is automatically executed and upon completion of any other program this program is again loaded and executed. Unlike any other program in the package, this program is placed on both program disks.

MINVEN/BAS - This program stores and prints out a record of Inventory of Market Animals, Feeders, and Poultry.

NETWORTH/BAS - This program surveys all credit and debit data entered and calculates a net worth statement. A copy of the statement is retained on the SPECIAL data diskette for later reference.

RECEIPTS/BAS - This program is used to enter and store receipts obtained. All receipt entries are made to the RECEIPTS data diskette and the identification file is updated to show the current number of receipt entries in the file.

REPORTER/BAS - This program is used to construct and print out cross reference reports to the user's specification. As its function is only to survey and collate data, it performs no file manipulation or bookkeeping operations.

RINVEN/BAS - This program stores and prints out a record of Inventory of Raised Breeding Livestock On Hand At End Of Year.

SUMMARY/BAS - This program totals and prints out monthly and year end records of receipts and expenses by each receipt and expense account category. These totals are posted to a special file on the SPECIAL diskette to be used by other programs such as ANALYSIS/BAS and NETWORTH/BAS.
